Abstract

Due to high production of palm oil, surplus quantities of palm oil wastes such as empty fruit bunches (EFB) and palm kernel shells (PKS) are generated. This study aims to analyze the characteristics of EFB and PKS ashes and their respective bio-silica content when combusted at different temperatures; 400°C, 600°C and 800°C. Several tests like weight loss, colour and Fourier Transform Infrared (FTIR) analysis are conducted. EFB records higher weight loss compared to PKS for all combustion temperatures, thus implying less silica content compared to the later. Both wastes also show the highest weight loss at 99.20% and 98.51% respectively, when they are burnt at 800°C than those combusted at lower temperatures. This happens because more impurities evaporate at 800°C, thus resulting in greater relative amount of silica in the ash. Colour analysis shows that the whiteness of both EFB and PKS ashes are the highest when combustion occurs completely at 800°C, particularly at 71.56 and 42.40 respectively. Besides, FTIR analysis depicts distinct presence of Si-O and Si-O-Si functional groups in both EFB and PKS ashes for all temperatures. It is also shown that combustion at 400°C are insufficient to remove impurities like hydroxyl groups, CH_2 components and organic compounds.

Keywords: *bio-based silica; colour; EFB; FTIR; PKS; weight*

1. Introduction

Silica or silica gel, is generally used to absorb excess moisture and has put forefront for process industries, refrigerant drying, insulating glass industry, as well as packaging desiccants and desiccant powder. Manufacturing pure silica uses intensive energy by smelting quartz sand with sodium carbonate at 1300°C [1]. Huge amount of energy is needed to operate the furnace in order to extract pure silica which contributes to much loss of heat and deteriorates the environment. In recent years, many researchers were concentrated in producing environment-friendly products to replace fossil fuels with renewable energy sources using biomass feedstock [2]. In conjunction with the increasing environmental issues, several studies are conducted to convert biomass wastes into beneficial products, for instance, the extraction of bio-silica from biomass wastes. The main key of research is to discover the possible alternatives of raw materials that can be burnt at lower temperatures than quartz and are able to produce bio-based silica.

As Malaysia is one of the world's largest producer and exporter of palm oil and palm oil products, the production of surplus quantities of biomass wastes is ample. Approximately 4 million tonnes of palm oil wastes are produced per year [3]. In the palm oil mills, only 10% of the fresh fruit bunches consists of palm oil, while the remaining 90% are discarded as wastes. On an average basis, 1 tonne of crude palm oil can be generated from 5 tonnes of fresh fruit bunches (FFB) [4]. Several researches on silica extraction from agricultural products, mainly rice husk ashes, have been done such as studies by Majumder et al. [5], Prasad and Pandey [6] and Della et al. [7]. However, limited study was found on the effects of temperature on the properties of the silica in the palm oil

wastes. Therefore, in this research, the properties of bio-based silica extracted from palm oil empty fruit bunch (EFB) and palm kernel shell (PKS) that are heated at temperatures of 400ºC to 800ºC are investigated.

2. Materials and Methods

The raw materials used as samples in this research are the main wastes from palm oil industries, namely, empty fruit bunch (EFB) and palm kernel shell (PKS). They are collected from Kilang Sawit FELCRA Berhad Samarahan, Kota Samarahan.

2.1. Sample Preparation

Prior to the experiments, all sample materials are prepared via acid washing and oven dyring, as illustrated in Fig. 1. The samples are washed with 1M hydrochloric acid (HCl) until pH 1 solution is obtained, before being dried in the oven at 60°C for 24 hours. The dried samples are then burnt in a furnace for 6 hours at three different temperatures; 400°C, 600°C and 800°C. The physical properties and functional groups of the ash samples are then analyzed.

2.2. Physical Properties Analysis

2.2.1. Weight Loss Analysis

Weight loss of samples after combustion is determined to observe its relationship with the silica content in the sample. To compute this, the basic formula for weight loss as shown in Eq. 1 is used in this research.

Weight Loss $= \dfrac{W_1 - W_2}{W_1} \times 100\%$ (1)

where W_1 and W_2 refer to the weights of the sample before and after combustion process respectively.

Fig. 1: Flowchart of sample preparation and analysis

2.2.2. Colour Analysis

The colour of the sample ash produced after combustion in the furnace is analyzed to determine the relative silica content in both sample ashes. According to Della et al. [7], the colour of the ash indicates the completeness of the combustion process. White ashes are produced only after complete combustion of samples occurs, as metallic impurities are removed effectively. Faizul et al. [1] also stated that incomplete combustion at low temperatures produces black or grey ash which is detected as inorganic impurities and unburned carbon amounts. Hence, high amount of silica is obtained when a white-coloured ash is produced.

To conduct colour analysis, the pixel data of the ash image is extracted using MATLAB in the form of RGB color space. The RGB color space is then converted into Lab color space whereby the value of Lab is then used to calculate the whiteness of sample using Eq. 2 [8]

$$WI = 100 - \sqrt{\left(100 - L^*\right)^2 + a^{*2} + b^{*2}}$$ (2)

where 'L' represents lightness while 'a' and 'b' represent redness (+) or greenness (-), and yellowness (+) or blueness (-) respectively.

2.3. Functional Properties Analysis

The functional groups of samples are important to determine the characteristics of the materials. Fourier Transform Infrared (FTIR) analysis is performed with ten number of scans, using FTIR machine by Shimadzu FTIR Spectrometer (MODEL: IRAFFINITY-1).

3. Results and Discussion

The section discusses on the results of three analysis which will help in achieving the objectives of this study. They include weight loss, colour and Fourier Transform Infrared (FTIR) analysis.

3.1. Weight Loss Analysis

The main procedure in producing an active bio-silica from palm oil waste ash is the heat treatment. This procedure is vital as it can minimise the carbonaceous materials and undesirable components present in the ash samples, thus increases the relative amount of

bio-silica in the samples. Table 1 illustrates the weight loss in the samples after 6 hours of calcination process.

Table 1: Weight loss of EFB and PKS after 6 hours of calcination process

Sample	Before (g)	After (g)	Weight Loss (%)
EFB 800	35.00	0.28	99.20
EFB 600	35.00	0.39	98.89
EFB 400	35.00	0.56	98.40
PKS 800	170.00	2.54	98.51
PKS 600	170.00	5.97	96.49
PKS 400	170.00	8.23	95.16

Based on Table 1, EFB records higher weight loss percentage compared to PKS at all combustion temperatures. It is as well observed that the weight loss of EFB and PKS burnt at 800°C are the highest compared to that burnt at lower temperatures of 400°C and 600°C. Besides, greater weight loss of samples indicates lower amount of Si available in the ash. Instead, the ash contains more organic components, water formed by reactions and volatile compounds, which will evaporate at high temperatures due to the decomposition of hemicellulose and lignin found in the crops [3]. The remaining ash should mostly consist of silica which is a non-combustible element. Hence, crops that have lower weight loss have higher silica content. In this case, PKS ash has slightly more silica compared to the ash of EFB, hence, indicating that more bio-based silica can be extracted from PKS than from EFB.

3.2. Colour Analysis

Table 2 tabulates the whiteness of EFB and PKS waste ashes computed using MATLAB. It is shown that EFB waste ash has the highest whiteness of 71.56 when combusted at high combustion temperature of 800°C, followed by the lower temperatures of 600°C and 400°C with whiteness of 60.93 and 17.22 respectively. Similar trend is as well observed for PKS waste ashes, whereby it records the highest whiteness of 42.40 at 800°C and lower whiteness of 37.09 and 17.29 at 600°C and 400°C respectively. This, therefore, indicates that highest amount of silica is present in both palm oil waste ashes produced at 800°C.

Table 2: Whiteness of EFB and PKS waste ashes

Sample	L*	a*	b*	Whiteness
EFB 800	71.71	-2.51	1.42	71.56
EFB 600	61.08	-1.51	3.03	60.93
EFB 400	17.58	1.27	-7.66	17.22
PKS 800	42.55	-0.60	-4.05	42.40
PKS 600	37.35	0.48	-5.73	37.09
PKS 400	17.70	-0.27	-8.19	17.29

3.3. FTIR Analysis

Fourier Transform Infrared (FTIR) is used to investigate the presence of the major functional group in the samples. The most important functional group in this study is the predominant absorbance peak of Si-O-Si asymmetric band stretching vibration which is between 1050 cm^{-1} and 1200 cm^{-1} [9] and the corresponding stretch at around 750 cm^{-1} to 864 cm^{-1} [10]. Besides, the intense peak in the range of 450 cm^{-1} to 470 cm^{-1} corresponds to the Si-O asymmetric bending vibration of Si-O-Si bond while peak between 2800 cm^{-1} and 3000 cm^{-1} represents the original organic compounds found in the crops [9]. The surface –OH groups of –Si-OH is indicated by the broad band from 1620 cm^{-1} to 1700 cm^{-1} as well as 3512 cm^{-1} and 3851 cm^{-1} [11]. Meanwhile, peak within the range of 2308 cm^{-1} to 2596 cm^{-1} indicates a CH_2 bond where the wavelength of the peaks decreases as temperature increases [11].

Fig. 2 and Fig. 3 illustrate the IR spectra for EFB and PKS ashes combusted at 400°C, 600°C and 800°C, whilst Table 3 summarizes the peak data obtained for both samples. Based on Table 3, both samples have absorbances in the range of 450 cm^{-1} to 470 cm^{-1} and 750 cm^{-1} to 864 cm^{-1}, at all combustion temperatures, which correspond to the Si-O asymmetric bending vibration of Si-O-Si bond and Si-O-Si asymmetric band stretching vibration respectively.

Both samples also display peaks within the band of 1050 cm^{-1} to 1200 cm^{-1}, which also indicates the presence of Si-O-Si asymmetric band stretching vibration in the sample waste ashes. These results imply that both palm oil waste (EFB and PKS) ashes have silica content for all tested combustion temperatures and hence, suggest that bio-based silica can be extracted from these wastes.

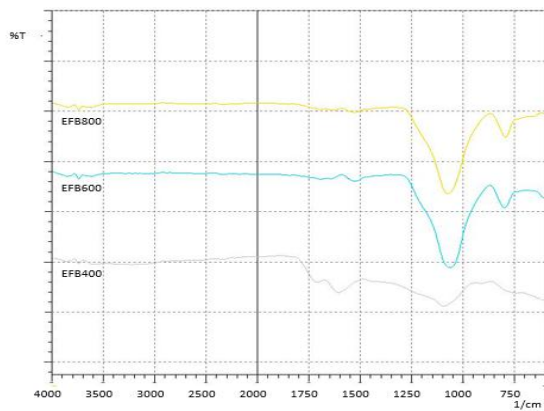

Fig. 2: FTIR spectra of EFB

Fig. 3: FTIR spectra of PKS

Table 3: Summary peaks (cm^{-1}) of EFB and PKS waste ashes

Sample	Peak (cm^{-1})		
	800	600	400
EFB	447.49	466.77	474.49
	792.74	798.53	744.52
	1076.28	1064.71	1097.5
	-	-	1686.79
	-	-	2320.37
	-	-	2823.79
	-	-	2889.37
	-	-	3608.81
PKS	474.49	457.13	464.84
	788.89	788.89	781.17
	1035.77	1033.85	1103.28
	-	-	2308.79
	-	-	2883.58
	-	-	2999.31
	-	-	3819.06

On the other hand, hydroxyl groups are observed only in the waste ashes produced at 400°C (EFB 400 and PKS 400) such that the peaks emerge within the ranges of 1620 cm^{-1} to 1700 cm^{-1} as well as 3512 cm^{-1} to 3851 cm^{-1}. This implies that –OH groups completely evaporate at higher temperatures of 600°C and 800°C. Apart from that, organic compounds and CH$_2$ bonds, which correspond to the bands of 2308 cm^{-1} to 2596 cm^{-1} and 2800 cm^{-1} to 3000 cm^{-1} respectively, are also found to remain in both EFB and PKS ashes burnt at 400°C. These results show that combustion process of EFB and PKS wastes at 600°C is sufficient to remove the hydroxyl groups, CH$_2$ compounds and other organic components, thus, increases the relative content of silica in both sample waste ashes.

4. Conclusion

This research compares the characterization results of two palm oil waste ashes, namely EFB and PKS, which are burnt in a furnace at three different temperatures; 400°C, 600°C and 800°C. Three investigations are conducted which include weight loss, colour and FTIR analysis. The results show that EFB has greater weight loss for all combustion temperatures compared to PKS. It is also proven that EFB and PKS wastes, burnt at 800°C, display the greatest weight loss than that combusted at lower temperatures of 400°C and 600°C. As greater weight loss of samples indicates lower amount of Si available in the ash, it is determined that EFB ash has slightly less silica compared to the ash of PKS. Besides, colour analysis proves that the greatest whiteness of ash is observed when EFB and PKS wastes are completely burnt at 800°C, which therefore, indicates the highest relative content of silica in these waste ashes. Furthermore, FTIR analysis shows distinct presence of Si-O and Si-O-Si functional groups in both EFB and PKS samples combusted at all temperatures, while other impurities, such as hydroxyl groups, CH$_2$ components and organic compounds, remain in the ashes when samples are combusted at 400°C.
